Hi all and welcome to the Yale Center on Climate Change and Health seminar series.

So today is our first spring seminar series and we are very fortunate to have Dr. Sarah Lowe joining us today.

Dr. Sarah Lowe is assistant professor at the Yale School of Public Health, the Department of Social and Behavioral Sciences.

Her talk today will be mental health after natural disasters, state of the research and a future directions.

I was told that this seminar was one of the most popular seminar series we had.

There were more than 80 participants registered after natural disasters, and we have another roughly 10 students.

So hopefully we can have a large audience today.

And before handing over to Sarah, I want to mention that we will have our Q&A section at the end of this seminar.

So if you have any questions please type in the chat box and I will raise the questions in the end.

So without further ado, Sarah the stages is yours.

All right, thank you very much for that Kai.

I’m going to share my screen and get to it.
Okay, so you can see my slides, yes?

- [Kai] Yes, yes.

Okay, awesome.

So as Kai said, I’m going to be talking about the research on mental health after weather related disasters, the state of the research and future directions.

And you’ll know what that I actually changed the name of my talk because the field is really moving away from referring to weather related or climate related disasters as natural disasters and acknowledgement of increasing findings showing that human beings are contributing to climate change and in turn increasing the frequency and severity of these types of events. And also that these disasters affects human-made structures and systems and people.

So it’s really an interaction between the environment and humanity. So I wanted to start off by giving...

Hold on just a second. An overview of my talk today.

I’m going to be first introducing myself and discussing my program of research. Then talking about the state of the literature on mental health after disasters, as well as some of the limitations they’re in.
And then give some examples of recent trends in the literature.
I’m gonna end by discussing some of my current and hopefully future work.

So starting off with my program of research.

I am a clinical psychologist by training.

I received my doctorate at the University of Massachusetts Boston which has, I think, unprecedented attention to social justice and multiculturalism.

After getting my PhD, I did a post-doctoral fellowship in psych Epi at Columbia Mailman School of Public Health.

And that’s where I really caught the public health bug and discovered that this would be a good home for me.

I then actually spent four years in the department of psychology at Montclair State University in New Jersey before coming to Yale.

This is my second year at the school of public health.

And I’ve had a really great experience so far and I’m happy to be here today and to be affiliated with the center for climate change and health.

My research program focuses on the long-term impacts of a range of potentially traumatic events.
So much of it has focused on climate related and weather related disasters. But I’ve also been involved in research projects after the deep water horizon oil spill, projects focusing on the impact of gun violence, sexual assaults, child maltreatment, and community violence. Work-related potentially trauma exposures among first responders, the impact of discrimination on the mental health and Muslim youth. And most recently I’ve been involved in studies of the intergenerational impact of the 1994 genocide against the Tutsi in Rwanda and the impact of the COVID-19 pandemic on vulnerable groups including healthcare workers and persons with disabilities. And I’d be happy to talk about any of this research in the Q&A. So that is me in a nutshell, and I’m gonna move on to discussing some of the work on mental health after disasters and giving an overview of the literature. So in 2018, my colleagues and I were asked to do a review of a year of research on the mental health impact of environmental disasters, as well as disasters like oil spills and nuclear explosions.
And when agreeing to do this I thought back

to the Seminole Review by Fran Norris

and colleagues in 2002, that reviewed all of

the literature

at the time on the psychosocial impacts of disaster.

And that review had included a total of 160 papers

on mental health and disaster.

So I said to myself this is one year it's probably gonna be less than that,

I can definitely handle that.

But then when my colleagues and I looked at the literature

in that single year, we found an enormous number.

We actually ended up narrowing our inclusion criteria

to those focused on PTSD and depression

as our two key outcomes

and only including quantitative research

just to manage our workload.

So I think this reflects the burgeoning interest in mental health after disasters, which is very exciting.

Nonetheless, what we saw in the literature

was consistent with prior research

in that most studies were cross sectional

and some included representative samples, and some did not.

So I just wanted to review

some of the mental health conditions that have been found

across studies of mental health after disasters.
So our review specifically focused on post-traumatic stress disorder and major depression but we know that these events are associated with increases in a range of mental health conditions such as acute stress disorder, which is sort of a precursor to PTSD, other conditions like generalized anxiety disorder and such symptoms that are concerning but don’t necessarily map nearly on to psychiatric diagnoses. Such as non-specific psychological distress internalizing symptoms, such as mood and anxiety symptoms in children. Externalizing symptoms including attention and conduct symptoms in children and adolescents, suicidality and adverse health behaviors including disruptions in sleep, eating and exercise. And what I would say is that there’s been considerable variation in the prevalence estimates of these conditions. And this is likely due to divergences across the studies for example, in the timing of assessment relative to the disaster, the exposure severity.
of the sample included as well as the disaster itself as well as other characteristics samples. However, across this literature something that has been consistent is that we’ve identified individual level risk factors at least at the cross-sectional level of adverse mental health outcomes. And here I’ve organized them by timing relative to the disaster, starting with a predict disaster factor. So what we know about people going into these types of events. Studies have pretty consistently showed that women, those of low socioeconomic status, those of low socioeconomic status, those with preexisting health conditions and in particular mental health conditions who are socially isolated, who have experienced previous exposure not only to disasters but other events are at increased risk for mental health adversity. Whereas findings regarding race and ethnicity age have been mixed. Turning to the peri-disaster period. So this is the period of the disaster itself and its immediate aftermath, we know that a range of experiences are associated with adversity.
including the perception that one’s life was in danger
experiences of physical injuries and bereavement and so on.
We also know increasingly that media exposure,
so exposure to versus details and images of disasters
in their aftermath are associated with increased severity
of psychiatric symptoms.
Reflecting the potentially broader impact of these types of events.
And then post disaster we know that when the storm clouds have cleared
and the earth has stopped shaking
disaster related stressors tend to persist.
And those who experienced financial strain, unemployment,
continue disruptions in their work and school lives,
stressors in their relationships tend to be at increased risk.
And that other stressful and traumatic life events,
whether or not they’re related to the disaster
tend to exacerbate disaster related mental health conditions.
So that in a nutshell is the research to date.
And I think what we’ve seen in the past five years or so
are some exciting ways in which researchers are trying to push the boundaries
of disaster mental health research.
So I have here some examples of recent trends. I know for those of you who read the review as part of the seminar you’ve seen examples of these already. But I’m gonna be focusing on on four trends and how my colleagues, students and I have in our work tried to push the field. So first focusing on long-term responses both in the general population and among vulnerable groups. Pathways to adversity, characteristics of communities and their impacts on mental health and treatment. So first off long-term responses. So what happens in terms of effective populations mental health not just in the immediate aftermath of disasters but in the longer term. And in this work, my colleagues and I have been very much influenced by the work of clinical psychologists and other scholars such as George Bonanno at Columbia and their theories about resilience. And other potential trajectories of mental health symptoms after exposure to a potentially traumatic event or PTE. And what Bonanno and colleagues have said is that most people when exposed to trauma will experience what has been termed resilience.
And resilience here means a trajectory of chronically low symptoms of distress and well being. So across studies, more than 50% tend to fall into this trajectory. However, other trajectories are common. About 25% on average experience what has been termed recovery. So short term elevations and symptoms and then smaller percentages have exhibited directories of chronic elevations and distress as well as delayed onset distress.

So my colleagues and I have worked within this area while also trying to push its boundaries and question some of the key tenants of this theory. As a first example, I’m going to be presenting data from the Galveston Bay Recovery Study. This was a study of... And I would say it’s probably the gold standard of disaster mental health studies that Sandra Golia and Fran Norris led where they were able to gather data from a representative sample of areas that were most severely affected by Hurricane Ike. And they collected three waves of data within the first two years. So it’s a really fantastic dataset.
So what we did is we ran a trajectory analysis not just of PTSD, but also of depression, functional impairment and days of poor health.

So I have our trajectory results here but they’re very small and with good reason, which is that I want to put across the takeaway message.

Which is that when we looked within each of these four domains resilience was indeed the modal outcome ranging from 45.1% to around 75% for PTSD. However, when we looked across all of these domains, we found that only 25% of our participants thereofabouts had resilience across all four.

Suggesting that a focus exclusively on PTSD or one other symptom domain might outscore the suffering and impacts of disasters on affected populations.

Now, something I would know here is that all the data for the study were collected prior to Hurricane Ike.

So we don’t know how the participants were doing beforehand. And it’s fairly likely that those who were experiencing elevated symptoms this had something to do with their wellbeing and health beforehand.

So in another study, I’ve been a part of...
the Resilience in Survivors of Katrina Project, we’ve been able to address this limitation. And so what the RISK project is, is a longitudinal study of about 1000 women. Most of them are single low-income African-American mothers who all experienced Hurricane Katrina. What’s very interesting about this study was that all of the participants were part of a study that was already going on prior to the hurricane called the Opening Door Study. But the Opening Door Study was a multi-site RCT of a community college intervention that sought to increase retention and graduation rates from community colleges throughout the country. And two of those colleges happened to be in New Orleans. So the hurricane hit in August of 2005 and both of those colleges were closed for the fall 2005 semester. But my colleagues, Jean Rhodes and Mary Waters were able to secure funding to launch a new study of resilience among those participants. And we’ve not collected data three times after the hurricane at approximately one, four and 12 years after Katrina.
And we just got back in the field last week to do an additional assessment of how they’re fairing amidst the pandemic. So I’m gonna be talking about two analysis we did with these data, looking at trajectories over time. The first was actually my dissertation. And for this project, we looked at patterns of non-specific psychological distress from prior to the hurricane to four years after the hurricane. So at the time, and actually I would say probably still it’s one of the few trajectory studies that had access to pre trauma data. So we were really able to look at how the patterns of symptoms over time might have been influenced by how people were doing before. And in a nutshell, we found a six trajectory solution and I know that this is a lot to look at. So I’m gonna try to break it down a little bit. So consistent with prior research, the modal trajectory was what we called resilience exhibited by over 60% of our participants. But what we can see is that those participants actually were doing well in terms of having low distress prior to the hurricane.
Similarly, other common trajectories in our sample were marked by consistency from pre to post disaster.

So we had a coping trajectory which may have looked like recovery and an increased trajectory which may have looked like chronically elevated symptoms.

But again, here we see that prior to the hurricane they had significantly higher psychological distress than those who were resilient.

Despite this consistency, we saw evidence for meaningful changes in distress.

So we actually had two trajectories that were marked by decreasing symptoms.

The first which we turned simply decreased had severe distress prior to the storm that decreased pretty consistently thereafter.

Another trajectory that we termed improved also had a severe distress prior to the storm.

And post disaster distress that was indistinguishable from those in the resilience trajectory.

So had we only had post-disaster data we would have assumed resilience.

And then we had a delayed trajectory consistent with prior research.

In a more recent analysis, we used our latest data.
to run a trajectory analysis this time specifically of PTSD symptoms. So because their PTSD symptoms had ties to the disaster, we only have them after the disaster. And here we did a trajectory analysis and examined pre trauma predictors of our trajectories. What was notable here is that we did not find what would typically be termed a resilience trajectory. That is a trajectory of consistently low symptoms. The healthiest trajectory in the sample had actually moderate PTSD symptoms that consistently decreased over time. So in my more recent work, I have been trying actually not to use the term resilience although I hate to muddy the waters. I think that resilience as a trajectory of consistently low symptoms maybe does not capture what it means to be resilience in terms of people’s lived experiences. So that’s one thing. The other thing we found in this analysis that I think is notable is that the most robust predictor of trajectory membership was having probable pre disaster mental illness. Disaster related exposures, including bereavement,
lack of vital resources like food, water and medical care and property damage were also predictive. Whereas other pre trauma factors seem to be mediated by either pre trauma mental illness or disaster exposure.

So for example, we looked at pre disaster social support and at the university level this was associated with trajectory membership but not when we controlled for pre trauma mental illness. Similarly, we had access to data on pre disaster physical health conditions. And we found that its association with trajectory membership reduced to non-significant once we control for disaster exposure. Suggesting that there might be some mediational pathways from these risk factors to outcomes.

Which brings me to the second area that I’m gonna be talking about today that I’ve observed in the disaster mental health literature which is an increasing focus on pathways. So pathways to both disaster exposure and even more so to post disaster mental health problems. Here my colleagues and I used what’s called a pre peri post disaster framework thinking about how risk factors
at these different time periods work together to shape disaster mental health. So for example, we would think that pre disaster factors not only increase post disaster mental health directly but they also increase adversity by influencing the extent to which people are exposed as well as the stressors they experience in the aftermath of disasters. Similarly, we think disaster related experiences are important for post disaster mental health both directly and in so far as they increase risk for further stressors downstream. And then finally we see the relationship between post-disaster stressors and mental health as being bi-directional in that post disaster stressors likely increased risk for mental health symptoms, but mental health symptoms in turn, make it more difficult to cope with post disaster stressors and actually can lead to more stressors in the post disaster environment. My colleagues and I recently published a paper testing such a model using data from the risk project. And we were specifically interested in the pathway from pre disaster trauma.
So we assessed trauma exposures separate from disasters including assaulted violence, bereavements, physical assaults, that sort of thing. And then we looked at both PTSD symptoms and generalized psychological distress symptoms. And today I’m just gonna be presenting the results from PTSD. So what we hypothesized was a bit of a complex model at least to look at. But we essentially thought that pre disaster trauma exposure would be directly associated with long-term post-disaster PTSD symptoms. So PTSD symptoms directly tied to one’s experience of Hurricane Katrina assessed at around 12 years after the hurricane. But we thought even more so there would be indirect pathways to variables downstream. Among them pre disaster psychological distress that these would work together and the likelihood of exposure to disaster related trauma, to short term post disaster PTSD symptoms and then also to post disaster trauma experiences. - And in a nutshell,
we found support for this type of model. The model had good fit with the data and most of our pathways were significant

Although notably in this model the path from pre disaster trauma to long-term symptoms was non-significant.

However, it had a significant indirect effect on long-term PTSD through other variables downstream.

Suggesting that people might have factors that increase their vulnerability to trauma across the board disaster related trauma and other types of trauma.

Which brings me to the third area of research that my colleagues and I have been focusing on, which is attention to community level factors and characteristics and exposures of communities that could increase or mitigate the impact of disasters.

So much of this research has been using data from the community resilience after hurricane Sandy study.

Which is a study we launched in New York city after the hurricane in 2012.
And what we did is a serial cross-sectional approach where we sampled two representative sub samples of survivors from highly effective neighborhoods within New York City. We gathered data from around 500 participants a year after the storm and 500 participants two years after the storm. We would have loved for the study to have been longitudinal but we did not have the funding to run that type of study so we took this approach instead. And we also gathered data on where our participants were living and community characteristics including property damage within the communities as well as demographic data from the American Community Survey. We were fortunate to have a health geographer on the team who did geospatial analysis including spatial autocorrelation analysis. In which we were able to identify clusters of low and high PTSD that were related to exposure but not entirely so. Suggesting that there might be unique characteristics of these different neighborhoods that could have increased or mitigate risk.
In another study, we looked at the interaction between exposures experience at the individual level. These included stressors like financial losses, displacement, and bereavement. Participants in communities that either experienced high or low levels of damages. And what we found was perhaps not surprisingly that individual and community level exposure had a synergistic effect on the likelihood of perceived need for mental health services. And that it was those who experienced both stressors themselves and who lived in communities that were highly damaged who had the greatest mental health needs. We've also using the serial cross-sectional data been able to look at interactions between individual and community level factors in shaping mental health risks over time. So there's one example we looked at the interaction between again individual level disaster related stressors in participants who are living in communities with either high or low unemployment. And what we found was that a year after the hurricane it didn’t matter whether our participants lived in higher or low unemployment areas.
at least for their PTSD symptoms. Across the board, hurricane related stressors were associated with elevated risk for PTSD symptoms. However, two years after the storm, the picture dramatically changed. And at this point, a disaster related stressors experienced at the individual level, their impact on post-traumatic stress disorder symptom severity was grossly exacerbated among our participants who were living in a high unemployment neighborhoods. And what this suggests is that the impact of community vulnerability might not manifest until the longer aftermath of disasters. And this is problematic because oftentimes the resources that are funneled to vulnerable communities are cut off at about the one-year anniversary. So this suggests greater needs over time. Which brings me to my fourth area that I’ve been seeing Burgeon in the research, which is a focus on treatment approaches. And I should say, I have not been involved in this research as much as I would like. But there are many different treatment approaches that I have received empirical support, including Psychological First Aid, Skills for Psychological Recovery, Project Hope in New York City,
Bounce Back Now, a smartphone-based app, focuses on a variety of mental health symptoms that could be experienced after disasters. TF-CBT and cognitive behavioral interventions have also been investigated in literature. So I’ve been involved, not in these treatment studies, but in studies using a system science approach to simulate populations or communities exposed to disasters and the potential impact of different ways of providing care. In this first study, we use data from our Hurricane Sandy study as well as studies of the effectiveness of different treatment approaches to create an agent-based model of New York City after Hurricane Sandy. We tested two different approaches to providing care. First was termed care, which was skills for psychological recovery applied broadly irrespective of our agent’s PTSD symptoms. We also then tried a step care approach where our agents were screened for their levels of PTSD.
the skills for psychological recovery intervention.

And those who had like the PTSD were given a more intensive treatment of cognitive behavioral therapy.

And through the simulation study, we found that the step care approach had benefits in decreasing the prevalence of PTSD over time as well as lead to cost savings.

We did a follow-up using the same data and adding on a social service case management approach.

And what we found here was that this approach had even greater benefits and reducing PTSD and across our population of agents in our simulation.

And in particular for those who experienced greater exposure to the hurricane characterizes having been displaced or losing income.

So while this is not a direct test of these types of interventions it represents an approach to system science to simulate and test different possibilities in effected populations.

So now I’m gonna turn to some of my current and hopefully future directions.

And for these, I have three.

The first is considering cumulative exposure which we think is important given that
we know that there are some areas within the United States and beyond that are disaster prone and have unfortunately experienced more than one environmental disaster as well as other stressors.

So one example of this is an analysis my colleagues and I did using data from the Gulf long-term follow-up study. And what we did is we looked at exposure amongst the sample to hurricane Katrina and the combination of these two different exposures. And what we found was that participants who were exposed to both disasters, both oil spill cleanup and hurricane Katrina tended to have higher mental health symptoms, including PTSD, depression and anxiety symptoms, as well as physical health symptoms, including headaches, back pain and digestive problems.

In a future project, I mentioned that we're collecting data on the COVID-19 experiences of our risk sample. And what we're hoping here is to investigate the impact of the pandemic on this group that has already been exposed to a major disaster.
and their perceptions of whether having experienced hurricane Katrina exacerbated the impact of the pandemic or help them cope.

Another future direction is that I’ve been increasingly interested in the broader impacts of climate change both on people living in areas that are affected by disasters and other climate change indicators, but more generally in the population even in less affected areas.

So for this work, I have had the honor of working with Susan Clayton, who is an environmental psychologist at the college of Wooster. And she, this past year developed and validated a measure of climate change anxiety.

So the two of us are working with a former classmate of mine, Sarah Schwartz, who’s a psychologist at Suffolk University on a study looking at college and graduate students on climate change anxiety, its relationship with mental health indicators such as depression and generalized anxiety disorder. And the protective role of constructs such as climate hope and climate activism, and mitigating this relationship.
And some of you in the climate change and health seminar may have been invited to participate in this study last semester. And then finally, I've been increasingly interested in other climate change indicators beyond disasters, including some of those that are more chronic and persistent. An example of this work I have had the honor of working with Kai Chen from the Yale Center for Climate Change and Health on a study looking at particulate matter, air pollution and its association with outpatient visits for mental health problems in Nanjing China. And what we found that was on days where there was greater levels of particulate matter the use of outpatient services increased. Suggesting that this environmental indicator could increase the demand for mental health services and also impact the likelihood of mental health symptoms. And then I've been collaborating on a systematic review trying to conceptualize climate change indicators and look at their impact on mental health.
This has been sort of slow going. I think in our initial screening we looked at around 12,000 abstracts and in doing so recognize the challenges of measuring chronic climate change impacts and their potential influence on mental health. So, hopefully that will come out in the next few years.

So that is actually all I’ve got for today. I think that was faster than I expected. But I have my email here and I would be happy to answer questions about this work both today and offline. So feel free to email me and reach out. I love connecting with people, hearing from students and so on.

So, thank you very much. Great, thank you Sarah for this wonderful presentation, giving the state or the knowledge regarding the mental health after all these weather related disasters. And thank you very much for sharing your future and the current directions in this field. It’s all, it’s very fantastic. And I’m sure the audience will have a lot of questions.

While the audience is preparing the question and typing in the chat box, we do have already clacking a question from the students.
So there are a lot of student questions. But the first question the student is wondering is you have shown different types of disasters especially in your review paper. Several students are kind of wondering is there a way to compare the mental health matters across different types of disasters? Like when you compare the different types of disasters, does this matter? Is a particular type of disaster has a strong effect on a particular mental health outcome? That is a really good question. So I know that it used to be said that disasters that were clearly human made such as oil spills and terrorism we’re likely to trigger more severe impacts on mental health because there was someone to blame and they seemed less fateful. However, I don’t think that has been shown empirically although perhaps someone else in this seminar knows more than I do. And I do think that it is again worth emphasizing that what we’ve typically seen as natural disasters do have a clear tie to climate change and human impacts and affects human made systems.
And I think that that can lead to feelings of anger and blame and neglect that can exacerbate risks sort of in the same way that would happen after a technological disaster or terrorism. So I think it’s difficult to really make the comparison. But my sense is that both have the potential to trigger symptoms across the board. Thanks, so another type of question follows the interventions you mentioned. The students are wondering, you have also mentioned your own research and other papers has shown some individual level or community level characteristics such as the employment rate that it can kind of modify the risk. So is there wave, can you talk about more this nonclinical intervention strategies? And are there community-based programs are happening or are there any further readings for the students? Yeah, so that is a really good question. So yeah, so as a clinical psychologist, I’m most well-versed in trauma-focused CBT and those types of treatments.
for people who have moderate or severe symptoms. But I think that there are public health approaches to treating mental health across the board including psychological first aid. And I think a key here is that psychological first aid acknowledges that most people are going to be resilient in terms of their mental health. And so aren’t going to benefit from more intensive services. And in fact, you know, therapeutic approaches might actually impede their coping processes and increase their risk. So psychological first aid as I understand, I have not been trained in it and I would love to at some point, focuses on assessing how people are doing, providing them information and then referring them to resources that help them. either with their mental health problems or other social service needs. I think a social service approach that integrates both psychological first aid and that assesses the broader range of post disaster needs and provides some case management in navigating the various systems that disaster survivors come into contact with is very important.
And I know that in our Katrina study so that was a mixed methods project a lot of our, not a lot, some of our survivors talked about how their encounters with social services after Katrina was actually their first touch point to getting mental health services for preexisting problems. So I think the post disaster period could actually be in some cases, an opportunity for people to get help that they needed all along. And it’s unfortunate that it takes a disaster to do that but could actually facilitate not just psychological growth but access to social and economic resources that foster their wellbeing across the board.

- Yeah, so that was a really interesting project to be a part of. So we use what’s called agent-based modeling which you actually put in, you create a population within a computer programming software.

- Oh, thanks, Sarah. I think there’s a question from the audience relate to this from Pat Haney. Just thank you, Sarah, can you give an explanation of the step heard care you discuss in your model?
We use Python and then you put in various inputs. You distribute disaster exposure, you distribute risk factors for psychopathology and then you can apply an intervention to that population. So intercept care approach, what I believe we did is we screened our participants meaning that we assign them different levels of PTSD. And then those who met a certain level I think we said seven PTSD symptoms who likely had the disorder were then given in the simulation cognitive behavioral therapy for PTSD. And that others who had non-zero but less than seven symptoms of PTSD were given quote unquote skills for psychological recovery. And based on the findings of prior research on the effectiveness of these two different intervention approaches our agents within the model, their symptoms declined in a way we would expect based on their socioeconomic demographics. So again, it was a simulation, it was not a test of an approach, but more of a demonstration that screening participants and providing services that meet their mental health needs.
could more effectively lead to decreases in PTSD over time.

- Oh, great, I think another, it’s not maybe a question
- but a comment from Massey asking
- as a clinician and a public health practitioner
- how best to translate this information
- to first advocate clinician to be aware now of these issues.
- So I think it’s first within the interaction question.

There has been other questions from students as well.

So while the students is asking
like we study the association between disaster
and the mental health, is that a case that is
some solution, will there be some underestimation
of their mental health status due to the stigma
especially in a lot of surveys you have performed?

- Yeah, so the question is whether
- mental consequences will be exacerbated
- if there’s stigma experienced?
- Or maybe underestimated in the service.
- Some people would maybe reclined
- to answer these questions, so.
- That is a good question.
- I don’t think I have a good answer for you.
- I think it’s certainly possible
- that people who experienced mental health stigma
might be less likely to report symptoms. That being said in these studies we use validated scales that ask about specific behaviors and experiences, not disorders. So for example someone who experienced mental health stigma might be more likely to say I haven’t had good sleep over the past two weeks, or I’ve been feeling like a lack of pleasure. Than saying that they experienced depression per se. So they are sort of behaviorally anchored questions. And it’s interesting ’cause I think people are more likely to report symptoms if they’re doing so anonymously, such as via an online survey or something like that. But a lot of, especially the epidemiologic studies are done over the phone, at least historically. And that having that personal contact could potentially be a barrier to reporting. And then absolutely stigma is a barrier to service seeking but you know, there are other barriers too. So in one study we looked at the frequency of different barriers and a major one was a lack of resources. So not knowing where services were,
not having time, needing childcare, not having transportation. And I think those can get in the way as well. Yes, another question kind of related to the respondents characteristics is, there’s one question from Peter asking, has any of the current research considered the difference in PTSD among first responders and long-term community responders versus those who are impacted but did not assist them with the response? Yeah, that is a really good question. So from the research that I’ve seen, epidemiologic studies have shown that people who are involved in the response tend to be at increased risk for mental health problems relative to the general population. However, there is substantial variability amongst first responders. So those who are exposed to atrocities, such as, dead bodies, people who are harmed really severe property damage, who are exposed to environmental toxins, like mold and things of that nature and who have not received adequate training. So I know for example, I think there was a study after the Deepwater horizon oil spill, or maybe not,
I'm trying to think. This may have been a disaster in one of the ones in Japan that was conducted that showed that people who were police officers or who had previously been involved in response work tended to have fewer adverse mental health impacts relative to those who volunteered. Which suggests the benefits and importance of resilience training prior to these exposures, which is really hard to do, right? Because these events by their very nature are unexpected and people are going to volunteer which is great to help out. There might not be adequate time to really prepare them, but probably at least some. - Great, so there’s a couple of other questions relating to the study. Actually to the review paper you presented. One of them is actually asking about not weather related disaster, but a question from the audience asking, have you worked or research interests such as with manmade disaster, such as armed conflict? And looking into the displacement and how these may impacted them in the house? - Absolutely, that’s a very good question.
So I have been involved in studies of human made disasters, namely the study I mentioned with the workers after the Deep Water Horizon oil spill but that seems very different than what the student is asking about which is armed conflict and displacement. I would love to get involved in this type of work. I haven’t yet had the opportunities. But what I can say is that there are some clear parallels to weather related disasters as well as some clear distinctions. So a parallel is that being displaced from your community not by choice can be really stressful and potentially traumatic. And that we found in our Katrina study, that those who relocated which was a good percentage of our sample tended to be at increased risk for mental health problems. Both those who like stably relocated who found a new place to live in a different state and settled there and those who had unstable housing trajectories. I think another commonality is that both types of community level trauma involve exposure to death and destruction.
But I think the particulars of it are very distinctive and the level of violence who is perpetrating it, the extent of displacement could be very different in ways that could exacerbate mental health risks.

So I think that there are some ways are similar and some ways they’re very different.

Yeah, I wanted a follow up on the like displacement request. And we know what you also mentioned the kind of anxiety conscience is your future direction.

So we know there’s issue on the counter refugees especially considering even the whiteflies in the West.

A lot of people just were displaced due to the whiteflies.

So when talking about to the mental health burden of these kind of refugees, can you give more like an explanation on the state of the science on that? And are there any new directions that you want to ask? Yeah, that is a really good question. In terms of the state of the science, I don’t know a lot of good literature on climate refugees and displacement aside from like domestic displacement after hurricane Katrina.
That doesn’t mean that there’s not good research going on,
I just might not know about it.
But my overall sense is there’s probably not a lot of it
going on and that this is to be a major issue
'tcause being displaced from one’s home community
either because your community has been destroyed
or that it’s at great risk is incredibly stressful.
And not only can impact mental health
but it can impact the things that foster mental health.
Such as social connections, employment,
community attachment, things of that nature.
So, you know, what I would say is that we need to be mindful
that this is going to happen
and trying to create communities that are accepting
and supportive of people who are displaced.
You know, I know for our Katrina sample
one of the things qualitatively that was very difficult
for them was moving to places where they were not welcome,
where they were stigmatized,
where they had difficulty getting jobs,
because they were from New Orleans.
Or heard people say things about people
from New Orleans and the culture of New Orleans
and this is within the same country.
So I could only imagine, you know, when we’re talking about people crossing international borders that these types of issues within communities are gonna be heightened. Yeah, another question kind of related to the culture inference, one of the students is asking among these community level characteristics, do you expect these different characteristics such as the culture inference can be a factor influencing the substantial variability you observed in the review paper on the premise of the PTSD and the depression? Yeah, that is a really good question. And I don’t know, offhand I’d have to actually look closely at the review paper that you all read at the particular year. What I would say having been involved in this research you know, we try to get community level data from the Census Bureau and the American Community Survey. And oftentimes when you run these analysis they explained very little variability in outcomes. And I think part of the reason is because census tracks and census blocks don’t necessarily
map onto what people perceive as their communities.

Like I know in after Hurricane Sandy I technically I was eligible for the study that we did. I have no idea what my census track was. And it would be hard to imagine that it really mapped onto what I saw as my community given that the people that I interacted with on a day-to-day basis didn’t necessarily even live in that particular census track. So I think it’s tricky.

And then an alternative source that people sometimes use is they ask people about their perceptions of their own community and that’s going to be biased by their mental health and functioning. So I think, you know, there are advantages and drawbacks to different approaches and very likely community level characteristics do shape mental health after disasters. But I don’t think we’ve been able to very precisely estimate that. - Great, so due to the time limitation we will have the last two questions. So the one is from Diane, excuse me, if I pronounce it wrong from the audience, what might the considerations be
for substance misuse services pre and post disaster?
And what has to be ensured to help these populations most?
- That is a really good question.
So I am not super well versed in substance abuse services.
I can say that there have been studies that have shown increases in alcohol use and use of other substances including non-medical use of prescription drugs after disasters.
and often they’re endorsed as a means of coping with stress.
And I think certainly we’ve seen that with the COVID-19 pandemic as well.
So I think in general a population-based approach could be to acknowledge that that is something that people do to cope.
and as well as the potential negative consequences of that.
and alternative ways of coping if people feel like using.
I do know anecdotally I have colleagues, not super close colleagues but contacts who have done some work.
with opioid and methadone maintenance after hurricanes.
And I think it’s really challenging.
because the people who run these clinics are also impacted.
And when people are displaced, they have disruptions in care.
that can be really devastating for their recovery.
So I think it is a major issue both in terms of people using substances to cope and people in recovery not only experiencing an additional stressor that can exacerbate their risk of abusing but also major disruptions in their care.
- Okay, so last question is actually from the student.

I'm trying to think if there are any other than the one that I presented today which looked at individual and community level exposures. I don't know of any offhand.

There is some work that has been done after the Nepal earthquake and tsunami.
that I believe found something in that effect.

But I can’t remember offhand what exactly they found.

And then there’s another study that was conducted after flooding in England by Compro, Winden and Compro, I know are their last names that found interactions I believe between exposure and social cohesion.

But social cohesion in that case was measured based on the participant’s own perceptions of social cohesion across the area.

So, yeah, those are two examples but I don’t know a ton of literature in that area.

And I think that is an open area for further explanation or examination.

Great, thank you Sarah. And I think there’s a lot of excitement to conduct research in this field and thank you all for listening today.

And just a reminder that this seminar is recorded and will be posted online on the Yale Center for Climate Change and Health.

so check out later.

With that, thank you Sarah.

Yeah, feel free to be in touch.

Thanks Sarah.
1106 00:54:27.630 --> 00:54:28.700 - [Sarah] Thanks Rob.
1107 00:54:28.700 --> 00:54:29.923 - Bye everyone.
1108 00:54:29.923 --> 00:54:31.923 - [Sarah] Bye everyone.
